Abstract

Social Networking Sites (SNSs) number at least 3.81 billion users worldwide, while in Greece, 74.7% of internet users resort to SNSs. However, there is no instrument adapted to the Greek language that assesses addiction to SNSs. The Bergen Social Media Addiction Scale is a short 6-item questionnaire that assesses social media addiction. This study aimed to evaluate the psychometric properties of the Greek version of the Bergen Social Media Addiction Scale. The sample consisted of 325 University students (mean age 21.6 years, SD=5.26). Confirmatory factor analysis was performed that supported the one-factor model. The reliability of the tool was tested with various indicators and was found to be satisfactory. The regression analysis identified gender, time of SNSs use, number of SNSs held by an individual and stress as statistically significant predictors of SNSs addiction. Positive correlations were found between SNSs addiction and stress, depression, anxiety and loneliness, while negative correlations were observed between SNSs addiction, self-esteem and age. Stress fully mediated the relationship between depression and SNSs addiction. The findings of the present study indicate that the Greek version of the Bergen Social Media Addiction Scale is a valid and reliable instrument for assessing SNSs addiction. The relationship between SNSs addiction and the biopsychosocial model was confirmed.

Introduction

Social Networking Sites (SNSs) are defined as online services that enable individuals to build a public or semi-public profile and give them the opportunity to create a network of contacts to be linked to (Boyd and Ellison, 2007). According to recent data, 3.81 billion of the global population maintain an account in at least one SNS, while worldwide internet users spend 144 minutes per day in SNSs (Global Digital Population, 2020). In Greece, 74.9% of internet users connect to make use of SNSs.

Internet addiction is not included in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-V) as a recognised disorder. However, one of the problematic aspects of internet, the internet gaming disorder (IGD), is described as a condition that requires further study (Petry and O’Brien, 2013; Yau et al., 2012). Several researchers have suggested that excessive use of SNSs should be characterised as addictive behaviour that falls into the broader category of internet addiction (Kuss and Griffiths, 2011; Yau et al., 2012). According to Kuss and Griffiths (2011), under the biopsychosocial model’s scope, SNSs addiction exhibits the common symptoms found in substance abuse. In summary, these symptoms include salience (behavioral, cognitive and emotional obsession with the use of SNSs), mood modification (use of SNSs leads to a favorable change in emotion), tolerance (need for increasing use of SNSs), withdrawal symptoms (unpleasant physical and emotional symptoms when the use of SNSs is limited or not for indexing
discontinued), conflict (intrapersonal and interpersonal problems due to the use of SNSs) and relapse (return to excessive use of SNSs after a period of abstinence) (Kuss and Griffiths, 2011).

Apart from the growing body of research about SNSs addiction, various psychometric instruments have been developed to assess this behaviour, such as the Bergen Facebook Addiction Scale (BFAS) (Andreasen et al., 2012) or the Facebook Intrusion Questionnaire (Elphinston and Noller, 2011). However, these tools focus only on Facebook, just one of the many SNSs (Griffiths, 2012). To resolve this issue, Andreasen et al. (2016) developed the Bergen Social Media Addiction Scale (BSMAS), an adaptation of the aforementioned BFAS and assessed SNSs addiction generally rather than one specific networking platform. Various studies have examined the psychometric properties of BSMAS. The scale has been validated in Italian (Monacis et al., 2017), Iranian (Lin et al., 2017), Hungarian (Bányai et al., 2017) and Chinese (Chen et al., 2020; Yam et al., 2019). According to the literature, addiction to SNSs has been positively correlated with depression (Shensa et al., 2017), stress (Vanman et al., 2018), anxiety (Atroszko et al., 2018), loneliness (Primack et al., 2017) and negatively with self-esteem (Hawi and Samaha, 2017). In addition, various demographic factors such as sex and age, appear to be associated with excessive use of SNSs (Andreasen et al., 2016). SNS addiction has also been linked to the duration of use (Koc and Gulyagci, 2013).

According to Hammen's stress generation hypothesis (1991), depressed individuals or individuals at risk of developing depression are influenced by their personal characteristics, beliefs and behavioural expectations in ways that will lead to stressful events in their lives. Therefore, individuals vulnerable to depression are more likely to experience more stressful events than less vulnerable individuals. The stress generation hypothesis has acquired a rather strong empirical documentation (Liu and Alloy, 2010; Starr et al., 2012).

The main objective of this study was to evaluate the psychometric properties of the Greek version of the BSMAS. In addition, the relationships between SNSs addiction with mental health variables (stress, depression, anxiety), personality variables (self-esteem), biological variables (age, gender) and behavioural variables (SNSs use time and SNSs number) were investigated. Specifically, the mediating role of stress in the relationship between depression and SNSs addiction was also examined.

Materials, Methodologies and Techniques

Participants and Procedure
Undergraduate students of the University of Athens, able to read and write in Greek, were eligible for participation in the study. After being fully informed of the research objectives and giving their written consent, participants were asked to complete a series of questionnaires anonymously. The completion time was approximately 15 minutes.

Translation Procedure
The BSMAS was translated to Greek and then back-translated by independent translators. The back-translation was then compared with the original scale, and adjustments were made as necessary. The final version was administered to eight people who were debriefed after completing the inventory to check for clarity and comprehensibility of the items.

Measures

Questions on time spent and number of SNSs accounts.
To evaluate the use of SNSs, questions regarding the hours spent on SNSs per day and the number of platforms in which the participants maintained an account were included. The question on time spent on SNSs was used to examine the criterion validity of the BSMAS. It has been argued that correlation coefficients of 0.30 to 0.40 are considered high (Alexopoulos, 2011).

Bergen Social Media Addiction Scale (BSMAS).
The BSMAS consists of six items representing key addiction elements (salience, mood modification, tolerance, withdrawal symptoms, conflict and relapse). Each item is answered on a five-point Likert scale ranging from 1 (very rarely) to 5 (very often). Regarding the structure of BSMAS, a unifactorial model has been identified (Andreasen et al., 2016; Monacis et al., 2017).

Depression Anxiety Stress Scale – 21 items (DASS-21). The DASS-21 consists of three 7-item scales that assess depression, anxiety, and stress. Every item is rated on a four-point Likert scale ranging from 0 (did not apply to me at all) to 3 (applied to me very much or most of the time). The Greek version of DASS-21 can be used as a reliable and valid instrument in the Greek non-clinical population (Pezirkianidou et al., 2018). The internal consistency of DASS-21 is acceptable (α = 0.85 for stress, 0.78 for anxiety and 0.87 for depression).

Rosenberg Self-esteem Scale (RSES). It consists of ten items that are answered on a four-point scale from strongly agree to strongly disagree. Five of the items have positively worded statements, and five have negatively worded ones. The scale measures self-worth by measuring both positive and negative feelings about the respondent’s self. Scores between 15 and 25 are considered average. It has been translated and validated in the Greek language (Galanou et al., 2013).

UCLA Loneliness Scale (UCLA). Emotions of perceived loneliness and social isolation were evaluated using UCLA, which is a 20-item instrument. Answers are rated on a four-point Likert scale (Anderson and Malikiosi-Loizos, 1992). The internal consistency of UCLA is acceptable (α = 0.89).

Statistical Analysis
To assess the construct validity of BSMAS, confirmatory factor analysis (CFA) was performed using the maximum
likelihood (ML) method. To assess the good-fitting of the model $\chi^2$ and its degrees of freedom (df) were used. For $\chi^2$ values associated with $p>0.5$ were considered good-fitting models, although it has to be mentioned that the $p$-value of this test is sensitive to large sample sizes. Besides, the root mean square error of approximation (RMSEA) with its 90% confidence intervals (CI), the standardised root mean square residuals (SRMR) and the comparative fit index (CFI) were used. For RMSEA values $< 0.06$ is acceptable while for SRMR values $< 0.08$. For CFI, values $>0.90$ were considered acceptable. Also, inter-item correlations were used to investigate the extent to which the items are evaluating the same content. An average inter-item correlation between 0.20 and 0.40 is considered ideal for the items to be homogenous enough while they contain sufficient unique variance (Piedmont, 2014). Finally, the standard error of measurement (SEM) was used to assess how the observed scores wavered from the measurement error. A value $\leq$ SD/2 is considered acceptable (Wuang et al., 2012). Bivariate correlations were used to investigate the associations between the variables of the study. A multiple regression analysis was employed to examine the predictive associations between the various variables of the study and SNSs addiction. Finally, a mediation analysis was performed to investigate the relationship between depression (independent variable), stress (mediator) and addiction to SNSs (depended variable). The mediation effect was assessed by the bootstrapping procedure (10,000 samples), which provides accelerated confidence intervals (95% CI) (Tabachnick et al., 2019). Statistical significance level was set at $p<0.05$. For the statistical analyses SPSS 26 and JAMOVI 1.2.5 were used.

Results

Descriptive statistics

The sample consisted of 325 undergraduate students (mean age 21.6 years, SD=5.26) of the University of Athens, among which 266 (81.8%) women and 59 (18.2%) men. Descriptive statistics of the study sample are presented in Table 1. Regarding the time participants spent daily on SNSs, 50%, 30%, and approximately 13% of the participants spent 1-3, 3-5 and over 5 hours, respectively.

Reliability analysis

The internal consistency of BSMAS was $\alpha=0.75$. The average inter-item correlation was relatively high ($r = 0.33$). Finally, the SEM (2.18) was equal to SD/2, which was acceptable according to SEM $\leq$ SD/2.

Correlation and regression analysis

BSMAS correlated statistically significant with all the study variables. The results are presented in Table 2. The results of the regression analysis are presented in Table 3. The model $[F(8; 316)=16.4; p<0.001]$ suggests that 24% (R$^2=0.236$) of the BSMAS variance can be explained through four statistically significant predictors. As shown

*BSMAS: addiction to SNSs. Time: hours spent on SNSs daily. SNSs: number of SNSs that an individual maintains an account. ANX: anxiety. DEP: depression. RSES: self-esteem. UCLA: loneliness/social isolation. * $p< 0.1$; ** $p< 0.01$; ***$p< 0.001$
in Figure 1, stress completely mediated the relationship between depression and addiction to SNSs (total effect, c: p<0.001; direct effect, c': p=0.103). The indirect effect (a*b) was statistically significant, b=0.127; p=0.007; 95% CI [0.0401-0.2222].

**Discussion**

To our knowledge, this study is the first that evaluated exclusively the SNSs addiction and how it is related to biological, social and psychological variables in a Greek sample of adult University students.

The results of this study confirmed the unifactorial solution as all the indicators of good-fit of the model were excellent and according to previous studies which examined the psychometric properties of BSMAS (Andreassen et al., 2016; Chen et al., 2020; Lin et al., 2017; Monacis et al., 2017; Yam et al., 2019). Besides, to improve the RMSEA index, a covariance path between the error terms in items 1 and 2 was added to the model. This finding is consistent with the studies of Monacis et al. (2017) and Yam et al. (2019). According to Monacis et al. (2017), this covariance can be justified by the theory. More specifically, in item 1, which examines the criterion of salience, the demonstrated distress in the behaviour may be related to the increased time of activity required to achieve satisfaction, which is also included in the criterion of tolerance, as expressed in item 2 (Monacis et al., 2017). On the other hand, Bányai et al. and Lin et al. did not report similar findings (Bányai et al., 2017; Lin et al., 2017). This could be explained by the fact that the samples of these studies consisted only of adolescents, while in the present study the sample concerned young adults. It has been suggested that differences in cognitive abilities between adolescents and young adults exist, which may lead to a different interpretation of the BSMAS item. At the same time, intercultural differences may also play a role (Lin et al., 2017).

All correlations were found to be statistically significant regarding the relationships between SNSs addiction and demographic, social and psychological variables. More specifically, positive correlations were found between SNSs addiction and stress, depression, anxiety and loneliness, while negative correlations were observed between SNSs addiction and self-esteem and age. These results are in line with the findings of previous studies (Andreassen et al., 2016; Atroszko et
al., 2018; Hawi and Samaha, 2017; Koc and Gulyagi, 2013; Primack et al., 2017; Shen et al., 2017; Vanman et al., 2018); the size of the correlation was similar to that found by others, which was between r=0.05 and 0.35 (Braïlovskaya and Margraf, 2018). The present study supported the biopsychosocial model with empirical data, as it highlighted that biological (age, gender) and psychological (stress, depression, etc.) factors are associated with addiction to SNSs.

Gender, time spent on SNSs and number of SNS accounts were found as predictive factors of addiction in this study. Regarding gender, it was found that women are more likely to be addicted to SNSs. This finding was consistent with the results of other validations of the scale (Andreasen et al., 2016; Hawi and Rupert, 2018; Monacis et al., 2017). It has been suggested that this may reflect a preference of women in activities that are characterised by social interaction and cooperation, while men show a preference for aggressive and competitive activities (Andreasen et al., 2016). As previous validations of the scale, this study found that time spent on SNSs was a significant predictor of addiction (Chen et al., 2020; Leong et al., 2019; Lin et al., 2017). In the study of Jafarkarini et al. (2016), time spent on SNSs was the only statistically significant predictor of addiction to SNSs. Also, the value of the correlation between the daily use of SNSs and addiction to SNSs (r=0.36; p<0.001) was considered high. It was found that the higher the number of accounts a user maintains, the more likely it is to become addicted to SNSs. This finding was consistent with the results of Pontes et al. (2018), who found that high-risk individuals maintained more accounts than the individuals which were at lower risk for developing SNSs addiction. In addition, this finding highlighted the importance of the transition from BFAS to BSMAS.

This study’s results, which are in accordance with other studies, highlighted stress as a predictive factor of SNS addiction (Braïlovskaya et al., 2018). Besides, according to the mediation analysis, stress was found to fully mediate the relationship between depression and SNSs addiction, which is consistent with Hammen’s (1991) stress generation hypothesis, stating that individuals vulnerable to depression experience more stressful events than non-vulnerable individuals. Subsequently, SNSs function as a stress-coping mechanism for their users. It has been found that vulnerable to depression individuals are more likely to use SNS to relieve stress than non-vulnerable to depression individuals (Braïlovskaya et al., 2019). This coping strategy could be helpful in the short term but could increase the risk for addiction to SNSs (Braïlovskaya et al., 2018). Furthermore, the increasing use of SNSs leads to various problematic behaviours (e.g. the user ignores intimate personal relationships), which activate a vicious cycle and negatively affect mood.

However, this study has some limitations. A test-retest examination was not held. Secondly, the sample mainly consisted of undergraduate students and primarily women, limiting the generalisation of the findings. Future studies should move in the direction of broader samples with respect to sociodemographic characteristics. Finally, the research data concerned self-report questionnaires, which are vulnerable to reporting bias.

In summary, the present study results indicated that the Greek version of the Bergen Social Media Addiction Scale is a valid and reliable instrument to assess SNSs addiction. Furthermore, it was found that biological (age, gender), psychological (stress, depression, anxiety, loneliness), and personality (self-esteem) variables are associated with addiction to SNSs. Gender, time spent on SNSs, number of accounts an individual maintains in SNSs and stress found to be predictive factors of SNSs addiction.

Key Points
• The Bergen Social Media Addiction Scale (BSMAS) is an instrument assessing Social Networking Sites (SNSs) addiction.
• The Greek version of BSMAS was validated in a sample of university students.
• The relationship between SNSs and the biopsychosocial model was confirmed.
• Gender, time of SNSs use, number of SNSs held by an individual and stress were identified as predictors of SNSs addiction.
• Stress fully mediated the relationship between depression and SNSs addiction.

Funding
This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.
